Cell Competition Drives the Growth of Intestinal Adenomas in *Drosophila*

**Highlights**

- In the fly gut $APC^{-/-}$ tumors kill surrounding cells and cause loss of healthy tissue
- Tumor-host cell competition fuels tumor growth
- JNK signaling boosts $APC^{-/-}$ adenoma growth and drives cell competition
- Differences in Yki activity determine the cell competition potential of $APC^{-/-}$ cells

**In Brief**
Suijkerbuijk et al. show that growing tumors in the adult *Drosophila* posterior midgut kill surrounding cells and cause host tissue attrition through a process called cell competition. Inhibition of cell competition prevents adenoma growth, indicating that it is an essential driver of tumor growth in this tissue.

SUMMARY

Tumor-host interactions play an increasingly recognized role in modulating tumor growth. Thus, understanding the nature and impact of this complex bidirectional communication is key to identifying successful anti-cancer strategies. It has been proposed that tumor cells compete with and kill neighboring host tissue to clear space that they can expand into; however, this has not been demonstrated experimentally. Here we use the adult fly intestine to investigate the existence and characterize the role of competitive tumor-host interactions. We show that APC−/− driven intestinal adenomas compete with and kill surrounding cells, causing host tissue attrition. Importantly, we demonstrate that preventing cell competition, by expressing apoptosis inhibitors, restores host tissue growth and contains adenoma expansion, indicating that cell competition is essential for tumor growth. We further show that JNK signaling is activated inside the tumor and in nearby tissue and is required for both tumor growth and cell competition. Lastly, we find that APC−/− cells display higher Yorkie (YAP) activity than host cells and that this promotes tumor growth, in part via cell competition. Crucially, we find that relative, rather than absolute, Hippo activity determines adenoma growth. Overall, our data indicate that the intrinsic over-proliferative capacity of APC−/− cells is not uncontrolled and can be constrained by host tissues if cell competition is inhibited, suggesting novel possible therapeutic approaches.

INTRODUCTION

It is increasingly recognized that tumors do not simply depend on their own proliferative capacity for growth, but instead interact with their environment on multiple levels. For example, the tumor microenvironment can have a growth-enhancing role by inducing a wound healing like pro-proliferative milieu [1] or by recruiting tumor enhancing cancer-associated fibroblasts [2, 3]. However, in certain instances, tumor-host interactions have also been reported to inhibit tumor growth [4]. For example, embryonic environments have been shown to suppress the aggressiveness of multiple cancer cells [5, 6]. In addition, in some contexts, fibroblasts have been shown to limit the growth and malignancy of neoplastic cells [7]. This suggests that understanding how to enhance the tumor suppressive properties of host tissues may help in the fight against cancer.

Reciprocally, it has also been suggested that precancerous lesions and growing tumors could adversely affect the host tissue. Specifically, it has been proposed that tumor cells could kill surrounding normal cells and use this strategy to clear space in which they can expand. This suggestion stems from the observation that in developing tissues, cells with tumor promoting mutations can induce cell death in nearby wild-type cells [8, 9]. In particular, it has been suggested that cancer cells co-opt a form of cell interaction normally present in tissues, known as cell competition [10, 11]. Cell competition was originally discovered in Drosophila when it was found that wild-type cells can kill cells with mutations that reduce their fitness and growth potential [12] and has been suggested to act as a quality-control mechanism to preserve tissue function [13, 14]. It was later found that in developing tissues, wild-type cells themselves could be killed via cell competition by mutant cells harboring oncogenic mutations, so called supercompetitor cells [8, 9]. This led to the long-standing hypothesis that tumor-host cell competition might take place and promote tumor formation; however, this has never been tested directly in adult tissues.

The adult Drosophila midgut has recently been established as a model system to study adult stem cell behavior, tissue homeostasis, aging, and regeneration [15–17]. This tissue has a high cellular turnover and is maintained by newly differentiated cells produced from intestinal stem cells (ISCs), in a way that is remarkably similar to the mammalian intestine [17]. Importantly, mutations that are involved in cancer have also been found to lead to overgrowth and tumor formation in the fly intestine [18–20], in some cases by niche appropriation [21]. Furthermore, we have recently shown that cell competition is active and plays a role in shaping tissue colonization in this tissue [22]. Overall, these features provide a unique opportunity to combine the power of Drosophila genetics and the simplicity of this adult homeostatic tissue to study the role of cell competition in tumor formation.

Here we show that Drosophila intestinal tumors compete with and induce elimination of surrounding cells, causing host tissue attrition. Importantly, we demonstrate that preventing cell competition, e.g., by inhibiting cell death, dramatically reduces tumor growth. Thus, by generating an environment permissive
for tumor growth, tumor-induced cell competition acts as a key driver of tumorigenesis in this tissue, providing a novel angle to counter tumor expansion.

RESULTS

**APC−/− Adenomas Induce Apoptosis in Surrounding Cells**

To investigate whether cell competition takes place at sites of pre-cancerous lesions, we used mutations in the *Adenomatous polyposis coli* (*Apc*) genes, which cause hyper activation of the Wnt pathway and induce hyperplasia and benign tumor formations (hereafter referred to as adenomas) in the adult *Drosophila* midgut [19, 20]. We focused on Wnt-induced adenomas because we previously showed that in developing tissues, cells with increased Wnt signaling can adopt a supercompetitor phenotype and cause elimination of normal cells [23]. In addition, the mechanisms driving *APC−/−* hyperplasia in the fly show important similarities with *APC−/−* intestinal adenoma growth in mammals (e.g., activation of the oncogene *myc* in *APC−/−* cells and dependence on Myc activity for adenoma growth [24]), making our study potentially relevant to the onset of this pathology.

To generate *APC−/−* intestinal adenomas, we introduced ISCs mutant for *APC1* and *APC2* (hereafter referred to as *APC−/−*) in the adult fly posterior midgut by flippase (FLP)-mediated mitotic recombination (Figure S1A). Clones derived from these cells were significantly bigger than control wild-type clones of similar age (Figures 1A–1C) and formed multi-layered structures bulging in the lumen of the gut (Figures 1D and 1E), as previously described [19, 20]. This distorted morphology is visible 10 days after clone induction (ACI; data not shown), but is more prominent at later stages. To address whether these adenomas induce apoptosis in the surrounding tissue, we monitored clone size over time (ACI) and specifically assessed whether cell death was induced around clones. To this end, we first stained control wild-type clones with anti-Prospero antibodies and anti-Delta antibodies to identify enterocyte, enteroendocrine, and intestinal stem cells, allowing us to determine which cells are eliminated. Clones derived from *APC−/−* ISCs were then stained for intact PARP (Figure 1A,B) or cleaved PARP (Figure 1C) to distinguish between living and dead cells. The intact cleaved PARP (Figure 1C) signal was used to detect apoptotic cells in the surrounding tissue at sites of adenoma growth (Figures 1D and 1E), whereas the cleaved PARP signal (Figure 1A,B) was used to compare clone sizes (Figure 1C). We confirmed that different regions of the gut (proximal, mid, and distal) were comparable in size (see Supplemental Experimental Procedures). Apoptotic cells were detected by immunostaining for cleaved PARP (red) (Figure 1A,B), and the ratio of cleaved PARP-positive cells at clone borders (near) normalized to the rest of the tissue (far) was measured and compared with controls (Figure 1C)

Throughout the figures, colored lettering describes fluorescent-protein-positive and white lettering fluorescent-protein negative tissue, and dashed lines indicate clone borders. Unless stated otherwise, in the graphs each dot represents one clone, red bars indicate median clone sizes, and p values are displayed above graphs (Mann-Whitney test). Detailed genotypes are listed in the Supplemental Experimental Procedures. Scale bars represent 50 μm.
cell competition, we then looked at the incidence of death in cells surrounding these clones. Using cleavage of PARP as a readout for caspase activation, we observed apoptotic cells in both control guts and guts containing APC−/− cells (Figures 1F–1G). However, although apoptotic cells were randomly distributed in control epithelia (Figures 1F, 1F′, and 1H, left graph), we found a 4-fold enrichment in apoptotic cells around APC−/− adenomas (Figures 1G, 1G′, and 1H, right graph). Increased apoptosis was observed both among the differentiated cell types, i.e., enterocytes (recognized by their large polyplloid nuclei; Figure 1I) and enteroendocrine cells (marked by expression of Prospero; Figure 1I), and among ISCs (marked by expression on Delta; Figure 1I′). Overall, we conclude that growing APC−/− adenomas induce elimination of nearby cells by apoptosis.

**APC−/−-Induced Cell Competition Causes Attrition of Healthy Tissue**

The increased elimination of cells surrounding APC−/− adenomas urged us to further examine the behavior of the host tissue in proximity of adenomas. By labeling the APC mutant and the wild-type chromosomes with different fluorescent markers, we could lineage trace simultaneously induced clones of cells originating either from APC−/− (RFP-negative) or from wild-type (GFP-negative) stem cells (Figure S1B). Interestingly, we found that wild-type clones were dramatically smaller when grown in midguts containing APC−/− adenomas (Figures 2B and 2C, right graph) than genetically identical control clones grown in wild-type epithelia (Figures 2A and 2C, left graph), with a median clone size of only ~25% of their expected size. In addition, we found that the number of wild-type clones per gut drops drastically over time (Figure S2A), with the majority of residual clones made by one cell only at 20 days ACI (Figure 2D), indicating accelerated clone extinction. Indeed, wild-type clones in control guts showed a much lower incidence of one-cell clones (Figure S2B). Altogether, these data indicate that APC−/− adenomas engage in cell competition with surrounding wild-type cells and, by acting as supercompetitors, cause attrition of the host tissue.

**Cell Competition Drives Tumor Growth**

Loss of healthy cells in a tumor-bearing environment is detrimental to organ function and compromises health [25]. Therefore, we next asked whether we could protect wild-type tissue from elimination induced by APC−/− adenomas by expressing inhibitors of apoptosis. Using the GeneSwitch system, which allows RU486 (mifepristone)-inducible Gal4-driven expression, we expressed the Drosophila Inhibitor of Apoptosis 1 (DIAP1) or baculovirus protein p35 directly after clone induction, across the posterior midgut in both progenitor cells and enterocytes [22, 26]. Remarkably, we found that inhibition of apoptosis by DIAP1 (Figures 3A–3C) or p35 (Figures S3A–S3C) expression was sufficient to fully restore growth of wild-type clones (Figure 3C; compare also to control clones in Figure 1C, left graph; p = 0.5694). This indicates that apoptotic induction alone can account entirely for host tissue attrition during cell competition.

Strikingly, the growth of APC−/− adenomas was drastically reduced in guts in which the loss of neighboring tissue had been prevented (Figures 3A′, 3B′, 3D, S3A′, S3B′, and S3D). In fact, the size of APC−/− clones was statistically indistinguishable from that of wild-type clones within the same guts (compare the right graphs in Figures 3C and 3D; p = 0.4211). This was not an indirect effect of inhibition of turnover, since wild-type clone growth was instead rescued in these same guts (Figures 3A–3C and S3A–S3C). In addition, DIAP1 or p35 expression did not affect the behavior of control clones in control guts (Figures S3E and S9F). Two complimentary experiments confirmed that
Figure 3. Cell Competition Fuels Tumor Growth

(A–D) Posterior midguts harboring WT clones (A and B) and APC<sup>−/−</sup> clones (A′ and B′). Clones are marked by 2×GFP (WT) or by the absence of GFP (APC<sup>−/−</sup>). In (B) and (B′), cell death was blocked by inducible expression of DIAP1 (+DIAP1; 40 µM RU486). Control guts (A and A′) are of the same genotype as in (B) but were treated with carrier only (−RU486). The graphs in (C) and (D) display the distribution of WT (C; left, n = 59 clones; right, n = 63 clones) or APC<sup>−/−</sup> (D; left, n = 87 clones; right, n = 161 clones) clone sizes.

(E–G) Posterior midguts harboring APC<sup>−/−</sup> clones marked by expression of GFP, with (F; +DIAP1) or without (E; control) additional expression of DIAP1. The graph in (G) displays the distribution of APC<sup>−/−</sup> clone sizes with (right) or without (left) DIAP1 expression (left, n = 172 clones; right, n = 187 clones).

(H–J) Posterior midguts harboring APC<sup>−/−</sup> clones marked by the absence of RFP. In (I), cell death was blocked in host cells by expression of DIAP1 (+DIAP1; 40 µM RU486). Control guts (H) are of the same genotype as in (I) but were treated with carrier only (−RU486). The graph in (J) displays the distribution of APC<sup>−/−</sup> clone sizes with (right) or without (left) DIAP1 expression in host cells (left, n = 160 clones; right, n = 218 clones).

See also Figure S3.
this effect is due to inhibition of apoptosis specifically in the host tissue. First, expression of DIAP1 or p35 only in APC<sup>−/−</sup> cells did not affect their clone size (Figures S3G–3H), ruling out an autonomous effect. Second, conditional inhibition of apoptosis exclusively in the host tissue (see Figures S1C and S1D for genetic setup) reduced growth of APC<sup>−/−</sup> adenomas to a similar extent as inhibition throughout the epithelium (Figures 3D and 3J; compare the right graphs in Figures 3D and 3J; p = 0.7212). Collectively, these data demonstrate that tumor-host cell competition is essential to drive the growth of APC<sup>−/−</sup> adenomas in the Drosophila adult midgut.

**JNK Signaling Boosts APC<sup>−/−</sup> Adenoma Growth Autonomously and via Cell Competition**

We next wondered which pathways are involved in APC<sup>−/−</sup> adenoma expansion. The Jun N-terminal kinase (JNK) pathway plays a fundamental role in modulating both cell proliferation and cell death in many tissues, including the fly intestine [27–29], and has been shown to be required for loser cell elimination in several types of cell competition [30, 31]. Using a phospho-specific antibody that recognizes an activated form of JNK, we observed high JNK activation specifically in guts that contain APC<sup>−/−</sup> cells (Figures 4B and 4B'; compare the right graphs in Figures 4B and 4B'; p = 0.7212). Collectively, these data demonstrate that tumor-host cell competition is essential to drive the growth of APC<sup>−/−</sup> adenomas in the Drosophila adult midgut.

Figure 4. JNK Signaling Boosts APC<sup>−/−</sup> Adenoma Growth

(A–B') Posterior midguts stained with anti-phospho (active) JNK (pJNK, red) containing WT (A and A') or APC<sup>−/−</sup> clones (B and B') marked by the absence of GFP.

(C–F) Posterior midguts harboring WT clones, marked by 2 × GFP (C' and D' and outlined in C and D), and APC<sup>−/−</sup> clones, marked by the absence of GFP (C' and D'). JNK signaling was blocked by inducible expression of Puckered (+Puc; 200 μM RU486; D and D'). Control guts (C and C') are of the same genotype as in (D) but were treated with carrier only (−RU486). The graphs in (E) and (F) display the distribution of clone sizes for WT clones (E; left, n = 38 clones; right, n = 44 clones) and APC<sup>−/−</sup> clones (F; left, n = 164 clones; right, n = 161 clones).

(G–J) Posterior midguts harboring APC<sup>−/−</sup> clones marked by expression of GFP with (H) or without (G) additional expression of Puckered within the clones and stained with anti-phospho H3 to mark mitotic cells (green) and anti-Delta to mark ISC (white). The graphs in (I) and (J) display the percentage of APC<sup>−/−</sup>/Deltapositive stem cells (i) or the percentage of mitotic APC<sup>−/−</sup>/Delta-positive stem cells per gut (J). Each dot represents one gut, and the black bar indicates the average (±SEM; left, n = 14 guts; right, n = 23 guts; t test).

(K–M) Posterior midguts harboring APC<sup>−/−</sup> clones marked by the absence of RFP. In (L), JNK signaling was blocked in host cells by inducible expression of Puckered (+Puc; 40 μM RU486). Control guts (K) are of the same genotype as in (L) but were treated with carrier only (−RU486). The graph in (M) displays the distribution of APC<sup>−/−</sup> clone sizes (left, n = 137 clones; right, n = 227 clones).

See also Figure S4.
Hyper-activation of JNK was prominent both inside APC$^{−/−}$ adenomas and in surrounding tissue (Figure 4B). This was not an effect of tissue aging [28] because increased pJNK signal could be observed as early as 5 days ACI (Figures S4C and S4D). Importantly, pJNK staining was still present within APC$^{−/−}$ clones in guts in which competition had been blocked by apoptosis inhibition (Figures S4E and S4F, arrowhead); however, its levels were reduced in small APC$^{−/−}$ clones (Figure S4F), indicating that clone size is important for JNK activation.

We next tested the relevance of JNK activation to APC$^{−/−}$ adenoma growth and cell competition. Interestingly, inhibition of the pathway throughout the gut epithelium, by GeneSwitch-induced expression of the JNK inhibitor Puckered (Puc), rescued APC$^{−/−}$ clones from host competition (Figures 4G–4H and S4G–S4I). This was accompanied by a reduction of Myc expression in host cells. Note that dependence on JNK activity for clonal expansion is not a general feature of ISCs, as JNK signaling inhibition has no effect on the colonization of wild-type cells in control guts [22]. Next, to dissect the role of JNK signaling in cell competition, we inhibited the pathway in non-tumor cells only. Importantly, inducible expression of either Puc or JNKDN specifically in the host tissue severely reduced growth of APC$^{−/−}$ adenomas (Figures 6A–6D, Figure S6A–S6D) in the host tissue did not affect the ectopic activation of diap1-LacZ, despite the severe reduction in clone size.

To test the involvement of Hippo signaling in cell competition, we aimed to level differences in Yki activity between APC$^{−/−}$ clones and their surrounding host tissue. Thus, we removed one functional copy of the upstream inhibitor kinase Hippo (hpo$^{−/−}$) or its upstream activator Expanded (ex$^{24}$) from the gut. Importantly, we found that halving the hpo or ex gene dosage fully rescued the growth ability of otherwise wild-type clones (Figures 6C–6F). This was not a consequence of a general hyper-proliferative response to hpo or ex heterozygosity, as it did not have any effect on clonal growth in otherwise wild-type guts (Figures S6E–S6H). Thus, imperfectly tweaking Hippo activity is sufficient to abrogate APC$^{−/−}$-induced cell competition in this tissue. Strikingly, the growth of APC$^{−/−}$ adenomas was severely reduced in hpo$^{−/−}$ or ex$^{24}$ heterozygous backgrounds (Figures 6C–6E’ and 6G). This is extremely unexpected, because removing one copy of a tumor suppressor should instead promote the proliferative potential of tissues. In contrast, the median size of these APC$^{−/−}$ clones reverted to that of wild-type clones in the same tissue (for hpo$^{−/−}$, compare Figures 6D and 6D’), suggesting that JNK signaling (Figures 6E and 6G; p = 0.3744; for ex$^{24}$, compare Figures 6E and 6E’ and the right graphs in Figures 6F and 6G; p = 0.7621). Importantly, this was not caused by a detrimental effect of Yki activity on APC$^{−/−}$ adenomas, because autonomous overexpression of Yki in APC$^{−/−}$ cells did not inhibit their growth (Figures S6I–S6K). Notably, the suppression of clone growth by inhibiting JNK signaling or silencing another reporter of Yki activity, was consistently upregulated in APC$^{−/−}$ clones (Figures 6A–6A’). Interestingly, diap1-LacZ upregulation was seen predominantly in small cells (Figures 6A–6A’, compare inset 1 to inset 2) and was observed throughout APC$^{−/−}$ clones and not just at clone borders, where cell competition takes place, suggesting that upregulation of Yki activity is autonomous to APC$^{−/−}$ cells and not a consequence of cell competition. Consistent with this, inhibiting cell competition by blocking apoptosis (Figures 6B–6B”) or JNK signaling (Figures S6A and S6B”) in the host tissue did not affect the ectopic activation of diap1-LacZ, despite the severe reduction in clone size.

Relative Differences in Hippo Activity Determine the Cell Competition Potential of APC$^{−/−}$ Cells

The Hippo pathway plays an important role in growth control and can inhibit proliferation and promote apoptosis via inhibitory phosphorylation of the downstream transcriptional co-activators YAP and TAZ (Yorkie [Yki] in Drosophila) [32]. Given that Hippo signaling has been implicated in cell competition in developing tissues [33–35] and that Wnt signaling induces YAP/TAZ activation in mammals [36, 37], we investigated whether Yki is active in APC$^{−/−}$ adenomas and whether it plays a role in cell competition. First, we observed that activity of the microRNA and Yki target gene bantam was high (Bantam-GFP levels were low) in some APC$^{−/−}$ clones (Figures S6A and S6B). Second, diap1-LacZ, another reporter of Yki activity, was consistently upregulated in APC$^{−/−}$ adenomas (Figures 6A–6A”). Interestingly, diap1-LacZ upregulation was seen predominantly in small cells (Figures 6A–6A”, compare inset 1 to inset 2) and was observed throughout APC$^{−/−}$ clones and not just at clone borders, where cell competition takes place, suggesting that upregulation of Yki activity is autonomous to APC$^{−/−}$ cells and not a consequence of cell competition. Consistent with this, inhibiting cell competition by blocking apoptosis (Figures 6B–6B”) or JNK signaling (Figures S6A and S6B”) in the host tissue did not affect the ectopic activation of diap1-LacZ, despite the severe reduction in clone size.

Tumor Growth Is Required for Cell Competition

By monitoring competing clones at 10 and 20 days ACI, we observed that wild-type clones initially grew (Figures 5A and 5C, left graph) and subsequently shrunk (Figures 5B and 5C, right graph). This coincided with an increase in APC$^{−/−}$ clone size (Figures 5A’, 5B’, and 5D), suggesting that APC$^{−/−}$ clones need to attain a critical size to compete efficiently. Indeed, blocking APC$^{−/−}$ clone growth by inhibiting JNK signaling or silencing of Myc [24] was sufficient to rescue wild-type clone size (Figures 5E–5J). We found that guts containing APC$^{−/−}$ clones with an average size of ~30 cells were able to outcompete wild-type clones (Figure 5A”; compare to control size in Figures 2A and 2C, left graph), indicating that this is a sufficient size for APC$^{−/−}$-induced competition. Notably, although myc is upregulated in Drosophila APC$^{−/−}$ intestinal adenomas and required for their overgrowth [24], we found that increasing Myc expression in host cells did not rescue their outcompetition (Figure S5B) or inhibit APC$^{−/−}$ adenoma growth (Figures 5K–5M). This indicates that, like in developing epithelia [23], differences in Myc levels are not required for APC$^{−/−}$-induced cell competition in the intestine.
**Figure 5. Tumor Growth Is Required for Cell Competition**  
(A–D) Posterior midguts harboring simultaneously induced GFP-negative WT (A and B) and RFP-negative APC-/- (A’ and B’) clones, dissected 10 days (A) or 20 days (B) ACI. The graphs in (C) and (D) display the distribution of clone sizes for WT clones (C; left, n = 179 clones; right, n = 74 clones) or APC-/- clones (D; left, n = 231 clones; right, n = 186 clones). (E–J) WT clones, marked by the absence of GFP, in posterior midguts harboring control APC-/- clones (E and H) or APC-/- clones expressing Pucker (F) or MycRNAi (I) specifically within the clone. The graphs in (G) and (J) display the distribution of WT clone sizes (G, left, n = 112 clones; G, right, n = 62 clones; J, left, n = 164 clones; J, right, n = 118 clones). (K–M) Posterior midguts harboring APC-/- clones marked by the absence of RFP. Myc was inducibly expressed in host cells (L; +Myc; 40 μM RU486). Control guts (K) are of the same genotype as in (L) but were treated with carrier only. The graph in (M) displays the distribution of APC-/- clone sizes (left, n = 119 clones; right, n = 114 clones). See also Figure S5.

APC-/- adenoma growth by hpo heterozygosity was not due to a reduction in JNK (data not shown) or JAK-STAT (Figures S6L and S6M) signaling. Altogether, these results show that Yki signaling is activated in APC-/- adenomas and plays a role in APC-/--induced cell competition in the intestine and that differences in Hippo signaling, rather than absolute Hippo activity, determine the cell competition potential of APC-/- adenomas.

**DISCUSSION**

It has been well over a decade since the first reports of a connection between cancer-related genes and cell competition [8, 9]. A recent study has demonstrated that Wnt-induced intestinal adenomas directly compete with the host tissue. Importantly, we find that cell competition is an essential driver of tumor growth. Indeed, inhibiting cell competition suppresses over-proliferation in APC-/- cells, effectively blocking tumor formation (Figure 7). Importantly, this finding demonstrates that the growth of cells with a mutation considered to be a major driver of colon cancer is not uncontrolled and that the cellular environment plays a deterministic role in the behavior of those cells. In this light, some previously reported observations might, at least in part, be explained by cell competition. For example, it has been reported that not all micro-metastases have the potential to immediately grow into secondary tumors [38], a phenomenon called cancer dormancy [38]. Based on our findings, we speculate that the interaction of such micro-metastasis with their environment, through cell competition, could play a deterministic role in their ability to grow or not. Consistent with this hypothesis, it has been shown that in developing Drosophila tissues cells with mutations in some tumor suppressor genes (e.g., lgl and scribble) can be eliminated by wild-type cells [39]. It is only through
acquisition of additional mutations (similarly to “second hit” mutations during tumorigenesis) that those cells overcome the tumor-suppressive environment of the host and overgrow [31, 40]. Furthermore, it has recently been found that naturally occurring cell competition in the thymus protects mice from developing leukemia [41], lending further support to this notion.

Recently, it has been shown that some mutations involved in human colon cancer can give a competitive advantage to cells in the mouse gut. Specifically, oncogenic mutations in K-Ras [42] or APC [43] endow stem cells with a competitive advantage, which increases their chances of colonization. On the basis of clone population dynamics, those studies have proposed that cell-autonomous differences in cell proliferation or cell survival rates among wild-type and oncogenically mutated cells account for their colonization bias. Here we have taken a different approach, whereby at the same time as scoring adenoma growth we monitored and manipulated the cell survival probability of the host tissue. This has allowed us to uncover cell interactions among tumor and host cells that cause induction of cell death in surrounding normal tissue, a feature that we demonstrate to be essential to enable adenoma growth. In light of our findings, we suggest that a similar process may contribute to the colonization bias observed in the mouse intestine [42, 43].

Figure 6. Differences in Hippo Activity Determine Cell Competition Potential of APC–/– Cells
(A–B′) Posterior midguts with APC–/– clones, marked by the absence of RFP 17 days (B) or 20 days (A) ACI. Yki activity was detected by expression of diap1-LacZ (white, A and B′; green, A, A′, B, and B′). The magnifications in (A) display regions inside (region 1) and outside (region 2) APC–/– clones, and arrowheads point at small APC–/– mutant (white arrowheads) or small WT (red arrowheads) cells. Cell death was blocked in (B) by inducible expression of DIAP1 (40 μM RU486). The magnifications display regions containing APC–/– clones, and arrowheads point at small APC–/– mutant cells.
(C–G) Guts containing simultaneously induced GFP-negative WT (C, D, and E) and RFP-negative APC–/– (C′, D′, and E′) posterior midguts. The graphs in (F) and (G) display the distribution of APC+/+ (F; left, n = 304 clones; middle, n = 155 clones; right, n = 120 clones) or APC–/– (G; left, n = 237 clones; middle, n = 183 clones; right, n = 198 clones) clone sizes from control (left), hpo+/+ (middle), or ex+/+ (right) guts. See also Figure S6.
We further show that growing APC−/− adenomas cause accelerated extinction of wild-type competing clones, resulting in attrition of surrounding tissue. This is remarkable, considering that it has been shown that APC mutations induce a cytokine-rich pro-proliferative environment in and around adenomas, which should instead promote growth [24]. This indicates that host tissues recede at sites of tumor growth, a process that is not only disadvantageous because it enhances tumorigenesis, but is also detrimental to organ performance. Since interfering with tumor growth inhibits competition and, vice versa, inhibiting cell competition blocks tumor growth, we propose that both events occur simultaneously and enhance one another in a feedback loop. Our finding that apoptosis inhibition allows the host tissue to contain growing adenomas could have important implications for cancer therapy, as it could provide a strategy to prevent or delay a lethal aspect of cancer, namely organ failure [25]. It further suggests that apoptosis inhibitors might constitute an unexplored arsenal in combination therapies against cancer. This is a radical suggestion, given that many anti-cancer chemotherapies and radiotherapies are, on the contrary, based on the use of wide-spectrum cell death inducers.

Our work identifies a new role for Yki activity in tumor growth. In particular, we show that APC−/− tumors display increased Yki activity, consistent with previous findings [36, 37]. Since YAP/TAZ and Yki are oncogenes, it is paradoxical that halving the gene dosage of hpo or ex, both of which are Yki inhibitors and recognized/putative tumor suppressors, should inhibit adenoma growth. This points at a new unappreciated role of Hippo signaling, which provides APC−/− adenomas with the ability to compete. Importantly, it further highlights that relative rather than absolute differences in Hippo activity are important for tumor growth. A hpo or ex heterozygous background (but, interestingly, not yki heterozygosity; Figures S6O and S6P) most likely limits the ability of Hippo to inhibit Yki in the host tissue. We show that although that has no noticeable effect on the behavior of otherwise wild-type cells under normal conditions, it is sufficient to allow them to withstand the competition from APC−/− adenomas. There are several possible mechanistic explanations for this observation. First, the Hippo pathway is an important sensor of cell density [44]. This might be relevant because APC−/− tumors disregard the normal morphology of the midgut epithelium and exhibit higher cell density [20] (Figure 1). Therefore, one could speculate that leveling Yki activity could give surrounding cells a chance to be less sensitive to cell density and thereby prevent cell competition. Alternatively, hpo or ex heterozygosity may confer some resistance to cell death induction, as one of the targets of Yki is the inhibitor of apoptosis DIAP1 [45].

Lastly, there is evidence that the crosstalk between Hippo and Wnt pathways is bidirectional and that, besides the previously discussed activation of YAP/TAZ by Wnt, the Hippo pathway can also restrict Wnt signaling [46]. Reduced Hippo signaling in surrounding cells could therefore act as a positive feedback to facilitate Wnt activation in these cells.

Finally, our findings also reveal an important role of the JNK pathway in APC−/−-driven adenoma formation. As we show, JNK activation in APC−/− cells and in patches of surrounding tissue is important to drive tumor growth. A similar activation of JNK has also recently been observed around, but not inside, intestinal Notch−/− tumors [21]. Interestingly, however, while Notch−/− tumors rely on the niche microenvironment to supply proliferative JAK/STAT ligands, we find that APC−/− tumors, which also require JAK/STAT activation [24], do not depend on a supply from the niche. Both JNK and JAK/STAT pathways are involved in sensing stress, injury, and inflammation and enabling regeneration and repair in the Drosophila adult gut [27–29]. This is particularly relevant because there are many

**Figure 7. Cell Competition Promotes Tumor Growth in Drosophila**

Schematic model depicting how cell competition affects surrounding cells and cause host tissue attrition. JNK signaling activation in APC−/− cells is required for their growth, whereas non-autonomous JNK activation in the host tissue is required for cell competition. APC−/− cells also display higher Yki activity than host cells and this is required for cell competition. Inhibition of cell competition prevents adenoma growth, indicating that cell competition is an essential driver of tumor growth in this tissue.

- APC mutation

Unperturbed

- Cell competition proliferation

- JNK

- Yki

- APC

- JNK

- Yki

- APC

Inhibition of cell competition

- Block apoptosis

- Reduce JNK activity

- Level Hippo activity

reports that inflammation and stress influence tumorigenesis. For example, colitis, induced by dextran sodium sulfate feeding, can strongly promote carcinogenesis in APC<sup>Min</sup> mice [47] and increase the colonization potential of p53 mutant cells [43]. Furthermore, it has been shown that chronic inflammation causes a predisposition for colorectal cancer [48], while treatment with anti-inflammatory drugs decreases this probability [49]. In this regard, we speculate that targeting JNK signaling could provide a particularly effective therapeutic strategy, as it could simultaneously inhibit cancer cell growth and protect host tissue from competition-induced attrition.

Overall, our findings shed light on new potential strategies for cancer treatment. They suggest that the growth of early lesions or micro-metastases could be more effectively prevented by strengthening the surrounding healthy tissue, in addition to focusing on killing the cancer cells themselves, which is the main goal of current treatments.

**EXPERIMENTAL PROCEDURES**

**Drosophila Genetics and Stock Maintenance**

Detailed information about the Drosophila stocks is given in the Supplemental Experimental Procedures, along with a list of all the experimental genotypes. Flies were grown at 25°C and fed on standard fly food containing yeast. For experiments using the GeneSwitch system [60], food was supplemented with 40 or 200 μM RU486 (mifepristone; Sigma-Aldrich, M8046) in 80% EtOH or with an equal volume of 80% EtOH as control. Single-stem-cell-derived clones were generated by mitotic recombination using the FLP/FRT (flippase recognition) system. 1 to 2 days after eclosion, fertilized female flies were heat shocked in a water bath at 37°C for 10 min. Adults were transferred to fresh vials every 2–3 days and were kept at 25°C until dissection at day 17 unless stated otherwise.

**Immunostaining**

Guts were dissected in PBS and fixed for 20 min at room temperature in PBS containing 3.7% formaldehyde and 0.025% Triton X-100. After several washes in 0.25% Triton X-100/PBS (washing buffer), guts were blocked for 30 min in a solution containing 3.7% formaldehyde and 0.025% Triton X-100. After several washes in washing buffer, guts were incubated for 2 hr at room temperature with the appropriate secondary antibody, followed by several washes in washing buffer. Samples were mounted in Vectashield (Vector Laboratories) on a borosilicate glass slide (no. 1.5, VWR International). A list of the antibodies used is given in the Supplemental Experimental Procedures.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Supplemental Experimental Procedures and six figures and can be found with this article online at http://dx.doi.org/10.1016/j.cub.2015.12.043.

**AUTHOR CONTRIBUTIONS**

S.J.E.S. and E.P. conceived, designed, and analyzed experiments. S.J.E.S. and G.K. performed experiments, with help from I.K. S.J.E.S. and E.P. wrote the manuscript with help from G.K.

**ACKNOWLEDGMENTS**

This work was supported by a Cancer Research UK (CRUK) Programme Grant to E.P. and G.K. (A12460); a Royal Society University Research fellowship to E.P. (UF0906580); an EMBO Long-Term Fellowship (ALTF 1476-2012), a NWO Rubicon grant (825.12.027), and a Dutch Cancer Society fellowship (BUIT-2013-5847) to S.J.E.S.; a Wellcome Trust PhD studentship to I.K.; and Core grant funding from the Wellcome Trust Core (092096) and CRUK (C6946/A14492). We thank Rafael E. Carazo Salas and Laura J. Wagstaff for discussions and/or critical reading of the manuscript and our anonymous reviewers for thoughtful and constructive feedback. We thank Emily Dudgeon and the Gurdon Institute Imaging and core facilities for technical assistance and members of the E.P. and S.J.E.S. labs for fruitful input and discussions. We also thank the Bloomington Stock Center (Indiana University) and scientists listed in the Supplemental Experimental Procedures for Drosophila strains and the Developmental Studies Hybrida Bork for antibodies. We apologize to the many researchers whose work could not be cited due to space limitations.
